\section*{ABSTRACT}

The majority of lower socioeconomic status (SES) households in the U.S. and Europe do not have stock investments, which is detrimental to wealth accumulation. Here, we examine one explanation for this puzzling fact, namely, that economic adversity may influence how people learn from financial information. Using experimental and survey data from the U.S. and Romania, we find that lower SES individuals form more pessimistic beliefs about the distribution of stock returns and are less likely to invest in stocks when these investments are likely to have good outcomes. SES-related differences in pessimism may help explain variation in investments across households.

\section*{1. Introduction}

A puzzling pattern in household finance is that more than 50% of people in the U.S. and Europe do not invest in the stock market (Campbell, 2006; Calvet et al., 2007). The avoidance of equity investments is particularly prevalent among those less well-off. Among households in the bottom quintile of the income distribution in the U.S., 89% have no stock holdings, while among those in the upper quintile, more than 82% have such holdings.\(^1\) From a policy perspective, it is important to understand the drivers of these substantial differences in the investment choices of households across the socioeconomic spectrum. Here we investigate a potential driver of these differences, which so far has received little attention in the literature, namely, that the beliefs held by people regarding the distribution

of returns in equity markets may be shaped by these individuals’ socioeconomic status. Specifically, we ask whether people’s socioeconomic status is related to the way they learn from financial information and make investment decisions.

Recent evidence suggests that encountering economic adversity has a significant influence on how people make economic choices, in particular by changing the way they learn from new information and form beliefs about future outcomes. Chronic poverty and bad economic shocks have been shown to be detrimental to cognitive performance (Hackman and Farah, 2009; Mani et al., 2013). Early-life adversity in particular has long-lasting effects on brain development and function, for example by changing the brain’s response to stress or by diminishing memory function (Evans and Schamberg, 2009). Poverty causes stress and negative affective states (Haushofer and Fehr, 2014), which may lead to suboptimal choices such as underinvestment in education, undersaving, or overborrowing (Banerjee and Duflo, 2007; Shah et al., 2012).

Aside from impeding decision-making in general, economic adversity is likely to also induce a pessimism bias in how people view the distribution of future outcomes they can attain. Specifically, neuroscience research has found that individuals who have experienced adversity exhibit a stronger brain response to negative outcomes, relative to positive outcomes. That is, those coming from more adverse environments display increased threat vigilance and a weaker response to rewarding outcomes (e.g., Nusslock and Miller, 2016; Hanson et al., 2016).

Therefore, the natural hypothesis that stems from these insights from neuroscience is that individuals coming from environments with more economic adversity, who are thus characterized by a lower socioeconomic status (SES), have more pessimistic beliefs about the outcomes of financial investment opportunities, and that these pessimistic beliefs arise from the fact that these lower SES individuals, unlike the rest of the population, will react less to good news relative to bad news about such investments. In other words, our current understanding about the effects of adversity on brain function suggests that economic adversity induces an asymmetry in how people learn from financial or economic news, such that those coming from lower SES environments will have a more pessimistic assessment of available economic or financial opportunities.

There is some indirect evidence from recent work in finance and economics that aligns with this prediction. Specifically, individuals who live through bad economic times or personally experience economic adversity subsequently avoid risky investments (Malmendier and Nagel, 2011; Knupfer et al., 2017), and those who experience sequences of negative financial outcomes form overly pessimistic beliefs about the future returns of risky assets (Kuhnen, 2015). Survey data indicate that people with less education have more pessimistic expectations about macroeconomic growth (Souleles, 2004).

In this paper, we use a controlled experimental setting to examine whether indeed people’s socioeconomic background is related to the way they learn from new financial information and make investment decisions. As hypothesized based on insights from neuroscience research, we find that lower SES participants form more pessimistic beliefs about the distribution of outcomes of risky financial assets—specifically, stocks—and are less likely to invest in these assets in situations when, objectively, they are likely to have high payoffs. This SES-related pessimism in beliefs is stronger when participants are actively investing, rather than passively learning, and when financial losses are possible. We replicate these experimental findings in samples from two countries—Romania and the U.S.—and then test the external validity of our experimental results by collecting SES, beliefs, and investment decisions data from a large non-laboratory sample of adults from all 50 states in the U.S. Across all these three populations, encompassing more than 1,400 people, we consistently find that low SES individuals are more pessimistic about the distribution of stock returns and are less likely to invest in stocks.

While there exists a significant literature in finance that studies potential reasons for the low observed stock market participation rate in the population, this literature has not focused on understanding the discrepancies in participation across people from different socioeconomic strata. The general pattern that stock market participation is limited has been attributed in the literature to three types of mechanisms: preferences concerning decision-making under risk, information regarding markets and financial concepts, and cost/benefit considerations. The preference-based explanations posit that people do not hold stocks due to risk aversion (Barsky et al., 1997), loss aversion (Dimmock and Kouwenberg, 2010), or ambiguity aversion (Dimmock et al., 2016). The information-based explanations suggest that people do not hold stocks due to low intelligence (Grinblatt et al., 2011), less developed social networks through which to learn about markets (Hong et al., 2004), or due to apprehension regarding financial institutions (Guiso et al., 2008). Finally, low stock market participation has been attributed to high participation costs (Vissing-Jorgensen, 2004) or to low benefits from learning about and investing in stocks (Kezdi and Willis, 2011; Lusardi et al., 2017).

Our results suggest that the lower participation in the stock market by lower income or lower education individuals is in part driven by these people’s pessimistic expectations about stock returns. However, it is possible that low SES individuals differ from higher SES ones not only in terms of their beliefs about stock market return distribution, but also in terms of the three broad categories of factors that have previously been related to low participation: preferences, information, and the cost/benefit tradeoff. The preference-related factors, though, do not seem to vary by SES levels. Specifically, there is no evidence that lower SES people are more loss-averse, more risk-averse, or more ambiguity-averse than others. In fact, more educated individuals are more ambiguity-averse (Dimmock et al., 2016) and more risk-averse (Jung, 2015), and those with higher incomes are more loss-averse (Gaechter et al., 2007). While preferences may not explain differences across SES levels in the propensity to invest in stocks, the other two categories of factors may be useful in understanding this SES-related variation in participating. Namely, it is possible that lower SES individuals possess less information about the stock market, or face a cost of obtaining such
information that is higher than the benefits of acquiring it (Vissing-Jorgensen, 2004; Kezdi and Willis, 2011; Lusardi et al., 2017).

Therefore, to isolate the role of the SES-related pessimism in beliefs that we focus on in this paper from any SES-related differences in access to information about stocks and opportunities to invest, or in incentives to learn about the stock market, it is critical that we use a laboratory setting where we can control for these other differences and isolate the SES-related differences in beliefs about the stock market.

Hence, as the first step in our study, we investigated in a controlled experimental environment whether learning from new information is related to people’s socioeconomic background. To do so, we invited participants from a top public university in Romania to a financial decision-making study, for which we used the same experimental design as in Kuhnen (2015). We ran the experiment at that university because there we can observe a large amount of variation in the socioeconomic status of the participant population, and, at the same time, a high degree of homogeneity in terms of scholastic achievement. Two institutional details lead to these features of our experimental setting: first, the students at this university are admitted based on their performance on a stringent, national-level exam; second, the Romanian government provides scholarships to all students who need financial assistance for covering the cost of attending this university, and 67% of those enrolled receive such aid.

We then checked whether the results from the original laboratory sample replicate in a different experimental pool of subjects, and conducted the experiment at a top public university in the U.S., where we verified that the findings from the original setting replicate out of sample, across the two countries.

Lastly, we sought to test the external validity of our laboratory results and collected data regarding beliefs about stock market returns and investment decisions from a large sample of U.S. adults across all 50 states. As expected based on the results of the laboratory experiments, we found that adults from lower SES backgrounds—namely, those with lower income, lower education, faced with significant recent negative financial shocks, or living in counties with lower incomes, lower education, or more unemployment—have a more pessimistic assessment of future stock market returns and invest a lower share of their income in stocks.

The controlled experiment done by our laboratory subjects required participants to complete two financial decision-making tasks. In the Active task subjects made 60 decisions, split into ten separate blocks of six trials each, to invest in one of two securities: a stock with risky payoffs coming from one of two distributions (good and bad), one which was better than the other in the sense of first-order stochastic dominance, and a bond with a known payoff. In each trial, participants observed the dividend paid by the stock, after making their asset choice, and then were asked to provide an estimate of the probability that the stock was paying from the good distribution. Therefore, the stock dividend history seen by each participant does not depend on whether or not they chose the stock. In other words, the asset choice did not change the learning problem faced by participants. In the Passive task subjects were only asked to provide the probability estimate that the stock was paying from the good distribution, after observing its payoff in each of 60 trials, which were also split into ten separate learning blocks of six trials each. In either task, two types of conditions—gain or loss—were possible. In the gain condition, the two securities provided positive payoffs only. In the loss condition, the two securities provided negative payoffs only. Subjects were paid based on their investment payoffs and the accuracy of the probability estimates provided.

Importantly, the learning problem and the information set faced by subjects was exactly the same, irrespective of their socioeconomic status. Hence, people’s estimate regarding the probability that the stock was paying from the good dividend distribution, namely, that distribution where the high outcome for that condition was more likely to occur than the low outcome, should not depend on whether a participant has encountered more or less economic adversity in life.

However, we find that low SES participants form subjective estimates for the likelihood that the stock is paying from the good distribution that are 2.86% lower than those of mid or high SES participants, in situations where objectively the stock is likely to be the good one. If subjects are actively investing and they are in loss condition trials, this wedge in beliefs becomes 4.70%. These results are robust to multiple approaches through which the low, mid, and high SES groups are constructed, and replicate out of the original Romanian sample, in a group of U.S. participants. This pessimism bias induced by low SES is not driven by differences in risk preferences or finance-relevant knowledge, but rather, by differences in updating from new information. In particular, we find that when high stock dividends are revealed, low SES participants update their beliefs less, by 3% to 5%, relative to mid or high SES participants. That is, lower SES participants are less likely to pay attention to good news about the available financial assets. We also show that while participants on average improve over time their ability to correctly estimate the probability that the stock is paying from the good distribution, the rate of improvement is slower for the low SES group relative to the others. Finally, we document that, relative to mid and high SES people, low SES individuals not only have a more pessimistic assessment of the stock outcome distribution when objectively the stock is likely to be a good investment, but they also are less likely to invest in the stock. We find that in cases when the stock is the optimal investment choice given the dividends observed so far, low SES participants are 5% less likely to choose the stock compared to their mid and high SES peers.

2 As the model and survey-based evidence in Kezdi and Willis (2011) suggests, it is possible that lower income individuals have weaker incentives to acquire information about financial markets, and hence their beliefs about stocks will be less accurate, compared to the beliefs of higher income individuals. Note that this incentives-to-learn mechanism does not predict that lower income individuals will be more pessimistic in their assessment of stocks; rather, the model in Kezdi and Willis (2011) predicts that people with lower incomes will have beliefs that are further away from what the historical return time series would imply.
We checked whether our laboratory results have external validity by employing an outside company (Qualtrics) to recruit on our behalf a sample of approximately 1,200 adults ages 18 to 65 across the U.S. and who were representative of the general population in terms of their income distribution. These adults resided in 591 different counties, across all 50 U.S. states. In line with the findings of our controlled experiments, in this non-laboratory sample we find that individuals from lower SES backgrounds are more pessimistic about the stock market and invest a lower share of their income in stocks. For example, we find that people whose household income is in the lowest tercile in the sample (i.e., under $35,000) on average estimate the probability that the aggregate U.S. stock market will have a positive return over the following year to be 47.70%, whereas the same subjective estimate is 58.69% for people whose household income is in the highest tercile (i.e., $75,000 or higher). At the same time, we find that the share of income invested in stocks is on average 7.94% for people in the lowest income tercile and 21.59% for people in the top income tercile. College-educated participants assess on average the probability that the U.S. stock market would have a positive return over the following year to be 55.46%, whereas the estimate provided by people without a college degree is 48.73%. Moreover, college-educated participants invest on average 19.07% of their income in stocks, whereas people without a college degree invest on average only 9.24% of their income in stocks. Also, individuals who, as of early 2015, have not encountered significant financial difficulties since 2007 assess the probability that the U.S. stock market will have a positive return over the next year to be 53.05%, whereas the estimate of those who have encountered financial difficulties since 2007 is 49.65%. Those participants without financial difficulties invest on average 16.79% of their income in stocks, whereas those who have encountered financial trouble invest only 9.07% of their income in stocks. When instead of participants’ self-reported own income, education, or indicators of negative financial shocks, we use objective U.S. Census county-level data regarding median household income, college education rates, or unemployment rates, we continue to find the expected results: namely, people residing in counties with worse economic conditions are more pessimistic about the returns of the U.S. stock market, and invest a lower share of their income in stocks.

The results in this paper could help shed light on the empirical pattern documented by Campbell (2006) and Calvet et al. (2007), namely, that U.S. and European households with lower education, income, or wealth are less likely to participate in the stock market. A potential driver of this pattern could be that lower SES households have more pessimistic beliefs about the possible outcomes of risky investments, as suggested by the findings in our study. Thus, overly pessimistic beliefs about risky asset returns may help explain why lower SES households are less likely to invest in equities.

Our findings contribute to the recent experimental finance literature on learning in markets and to the household finance literature on stock market participation. Payzan-LeNestour and Bossaerts (2015) show that people can learn about financial assets according to Bayes’ rule, if changes in the outcome distributions of risky assets are made salient. If that is not the case, learning performance deteriorates significantly. Beshears et al. (2013) find that investors are unable to learn well from processes that mean-revert slowly. Investors’ learning process depends, incorrectly, on their prior investment choices (Kuhnen et al., 2015) and prior choices suboptimally influence future trading decisions (Frydman and Camerer, 2016). Beshears et al. (2015) find that low income individuals reduce their investment rates upon learning about the contributions to retirement accounts of their work peers, and suggest that discouragement from social comparisons may drive this effect.

We describe the experimental design in Section 2. In Section 3 we present the main result, as well as robustness checks, tests of alternative explanations, and external validity tests. We discuss implications of the pessimism bias induced by encountering economic adversity and suggest avenues for future research building on this finding in Section 4.

2. Experimental design

For the controlled laboratory experiment we recruited 203 participants (53 males, 150 females, mean age 21.3 years, two years standard deviation) via on-campus flyers at the Babes–Bolyai University, which is a top higher-education institution in Romania. Participants gave written informed consent, as required by human subject protection rules. All payments to participants for their performance in the experiment were provided in RON, which is the local currency. (One RON is approximately equal to 0.3 USD.) Following the same experimental protocol as in Kuhnen (2015), each participant completed two financial decision-making tasks, referred to as the Active task and the Passive task, during which information about two securities, a stock and a bond, was presented. Whether a participant was presented with the Active task first, or the Passive task first, was determined at random. Each task included two types of conditions: gain or loss. In the gain condition, the two securities provided positive payoffs only. The stock payoffs were +10 RON or +2 RON, while the bond payoff was +6 RON. In the loss condition, the two securities provided negative payoffs only. The stock payoffs were −10 RON or −2 RON, while the bond payoff was −6 RON. The task included gain and loss blocks, in both the active and passive version, as learning may differ across these settings (Kuhnen, 2015).

In either the gain or the loss condition, the stock paid dividends from either a good distribution or from a bad distribution. The good distribution is that where the high outcome occurs with 70% probability in each trial, while the low outcome occurs with 30% probability. The bad distribution is that where these probabilities are reversed: the high outcome occurs with 30% probability, and the low outcome occurs with 70% probability in each trial.

Each participant went through 60 trials in the Active task, and 60 trials in the Passive task. Trials are split into “learning blocks” of six: for these six trials, the learning
Table 1
Experimental design.

Each participant goes through 60 trials in the Active task, and 60 trials in the Passive task. Whether the participant does the Active task first, or the Passive task first, is determined at random. Trials are split into “learning blocks” of six: for these six trials, the learning problem is the same. That is, the computer either pays dividends from the good stock distribution in each of these six trials, or it pays from the bad distribution in each of the six trials. The good distribution is that where the high dividend occurs with 70% probability in each trial, while the low outcome occurs with 30% probability. The bad distribution is that where these probabilities are reversed: the high outcome occurs with 30% probability, and the low outcome occurs with 70% probability in each trial. At the beginning of each learning block, the computer randomly selects (with 50%–50% probabilities) whether the dividend distribution to be used in the following six trials will be the good or the bad one. There are ten learning blocks in the Active task, and ten learning blocks in the Passive task. In either task, there are five blocks in the gain condition, and five blocks in the loss condition. The order of the blocks is randomized. An example of a sequence of loss or gain blocks that a participant may face is shown below.

The probability estimate that the stock was paying from the good distribution, after observing its payoff in each of 60 trials (split into ten learning blocks of six trials each, as in the Active task), Fig. 2 shows the time line of a typical trial in the Passive task, in either the gain or the loss conditions. In the Active task participants were paid based on their investment payoffs and the accuracy of the probability estimates provided. Specifically, they received one-tenth of accumulated dividends, plus ten cents for each probability estimate within 5% of the objective Bayesian value. In the Passive task, participants were paid based solely on the accuracy of the probability estimates provided, by receiving ten cents for each estimate within 5% of the correct value. Information regarding the accuracy of each subject’s probability estimates and the corresponding payment was only provided at the end of each of the two tasks. This was done to avoid feedback effects that could have changed the participants’ strategy or answers during the progression of each of the two tasks.

This information was presented to participants at the beginning of the experiment, and is summarized in the participant instructions sheet in Appendix A. The experiment lasted 1.5 hours and the average payment per person was 28.69 RON.

The value of the objective Bayesian posterior that the stock is paying from the good distribution can be easily calculated. Specifically, after observing t high outcomes in n trials so far, the Bayesian posterior that the stock is the good one is: \[ \frac{1}{1 + \frac{p^n}{q^t}} \] where \( p = 50\% \) is the prior that the stock is the good one (before any dividends are observed in that learning block) and \( q = 70\% \) is the probability that a good stock pays the high (rather than the low) dividend in each trial. Appendix B provides the value of the objective Bayesian posterior for all \( n, t \) pairs possible in the experiment. This Bayesian posterior is our benchmark for measuring how close the subjects’ expressed probability estimates are from the objectively correct beliefs.

For each participant we also obtained measures of their financial literacy and risk aversion. We obtained these two measures by asking subjects two questions regarding a portfolio allocation problem, after they completed the Active and Passive investment tasks. These questions are described in Appendix C. Briefly, the first question asked how much of a 10,000 RON portfolio the participant would allocate to the stock market and how much to a savings account. This answer provides a proxy for their risk preference, measured outside of the financial learning experiment. The second question asked the person to calculate the expected value of the portfolio they selected, and through multiple-choice answers could detect whether people lacked an understanding of probabilities, of the difference between net and gross returns, or of the difference between stocks and savings accounts. This yielded a financial knowledge score of zero to three, depending on whether the participant’s answer showed an understanding of none, one, two, or all three of these concepts.

Participants also completed an 11-item numeracy questionnaire as in Peters et al. (2006), which measured their ability to do simple algebraic calculations and use information about probabilities.
Fig. 1. Active task. An example, translated in English, of a gain condition trial (top panel) and a loss condition trial (bottom panel). In either type of trial, subjects first choose between the stock and the bond. Then they observe the dividend paid by the stock that trial, no matter which asset they chose, and then are reminded of how much they have earned so far from the payoffs of the assets chosen so far in the Active investment task. Lastly, they are asked to provide an estimate for the probability that the stock is paying from the good dividend distribution, and their confidence in this estimate.

Our main measure of socioeconomic status for this sample of young adults is obtained as in Ensminger et al. (2000) by aggregating information we obtain from each participant regarding their parents’ income and education, their family size, and closeness of family ties. We split the overall group of 203 participants into a low SES subsample (67 individuals), and a mid or high SES subsample (136 individuals), based on whether their aggregate SES score is in the low third or the upper two thirds of the SES scores distribution. As a second way to measure SES, we split the sample depending on whether the parental income is below or above 1,000 RON/month (approximately $300), which is the minimum full-time wage in Romania. As a third way to measure SES, we split the sample based on whether the participants’ subjective assessment of whether they rank in society on a scale from one to ten is below five. Finally, as a fourth way to measure SES, we split the sample based on whether neither of the participants’ parents have a college degree.
3. Results

3.1. Main result

We find that low SES participants, relative to medium or high SES ones, form more pessimistic beliefs about the distribution of outcomes of financial investments when, objectively, these investments are likely to be good. This effect is shown in the simple univariate analysis in Fig. 3, where we present the average subjective probability estimate that the stock is paying from the good distribution, for each level of the objective Bayesian posterior probability, separately for low SES participants, and for mid or high SES ones. As the figure shows, there is no significant difference in the subjective posteriors of low SES individuals relative to the rest of the sample, in situations where the objective posterior that the stock is the good one is below 50%.3 However, when, objectively, the probability that the stock is the good one is greater than or equal to 50%, low SES participants have an assessment that

---

3 When pooling together all trials for which the objective posterior is less than 50%, the difference in beliefs between the low SES subjects and the rest of the participants is 1.50%, and it is insignificant at conventional levels (p = 0.41). The largest difference between SES groups is observed when the objective posterior is equal to 1.43% (the second smallest possible level of posterior belief in this experiment, as can be seen in Appendix B). There are 336 trials when this occurs, and in these trials, low SES subjects provide estimates that are on average significantly higher (p < 0.05) than those of the rest of the participants. Note, however, that these trials only make up 1.41% of all observations in the experiment, hence they do not have a sizeable effect on the overall difference in beliefs between low SES subjects and their peers.
is on average 2.98% more pessimistic than that of the mid and high SES participants. This difference is significant at \( p < 0.05 \).

Fig. 3 also shows that irrespective of their SES level participants produced estimates that were too high when the objective posterior was low, and too low when the objective posterior was high. This is in line with the well-documented conservatism bias (e.g., Peterson and Miller, 1965; Phillips and Edwards, 1966), whereby people update their prior in the correct direction, but not sufficiently. This phenomenon was also noted in a different analysis in a sample of participants recruited at Northwestern University in the U.S. (Kuhnen, 2015), but it is more pronounced in the sample of Romanian subjects. Among the Romanian participants, the average deviation in beliefs from Bayesian posteriors was 28%, whereas among the Northwestern participants, the average deviation was 14%. Such conservative updating can occur if subjects do not fully trust or understand the information presented during the experiment. While not the focus of the current paper, these cross-country differences in conservatism are quite striking and may relate to two cultural differences documented by prior work, namely, that relative to Americans, Romanians are less likely to trust others (Algan and Cahuc, 2014) and are less financially literate (Klapper et al., 2015).

To further investigate our main result of interest, namely, the role of SES on the level of beliefs regarding stocks’ dividend distribution, in Table 2 we conduct regression analyses where we estimate the effect of the low SES indicator on subjective probability estimates. In these regressions we control for participants’ gender and age, and include fixed effects for the level of the objective posterior probability. Standard errors in these regressions and throughout the rest of the analysis are clustered by participant.

In Table 2 we replicate the main result shown in Fig. 3. We find that low SES participants have beliefs that are 2.86% (\( p < 0.05 \)) more pessimistic relative to the mid or high SES participants regarding the likelihood that the stock is paying from the good distribution, when the objective probability that this is the good stock is greater than or equal to 50%. When objectively the stock has a strictly less than 50% chance to be the good one, there is no SES difference in subjective probabilities. We can reject (\( p < 0.05 \)) the hypothesis that the effect of low SES on the subjective estimate of the probability that the stock is the good one is the same for situations when objectively this probability is strictly below 50% (first column in Table 2) as when it is equal to or higher than 50% (second column in Table 2).

Moreover, the regressions in the leftmost four columns in Table 2 show that the pessimism bias regarding risky investments that is related to coming from a low SES environment is particularly strong if participants are actively investing, rather than passively learning, and if financial losses are possible. In these types of trials (i.e., in the

4 In unreported models similar to the regression in the second column in Table 2, we show that low SES has a significant and negative effect on the subjective probability that the stock is paying from the good distribution separately in situations when the objective probability is strictly below 50%, as well as when it is exactly equal to 50%. The estimated effects of low SES on the subjective probability in these two subsets of trials are −2.65% (\( p < 0.1 \)) and −3.6% (\( p < 0.05 \)), respectively. Hence we group these two subsets of trials together (i.e., these are the trials when the objective probability that the stock is the good one is equal to or greater than 50%) in the main analysis.
The regressions in the four panels of the table are estimated as in Table 2. A different measure of socioeconomic status is used in each panel. The dependent variable in the OLS regressions in the table is \( Probability \ estimate_i \), which is the subjective estimate for the probability that the stock pays from the good dividend distribution, given the dividend history seen by participant \( i \) up to and including trial \( t \). The variable Low SES, is an indicator equal to one for participants in the bottom third of the SES score distribution. The variable Low parental income, is an indicator equal to one for participants whose parents have a combine income of less than 1,000RON (approx. $300) per month. The variable Low SSS, is an indicator equal to one if the person's subjective assessment of their socioeconomic status is less than five, on a scale from one to ten. The variable Low parental education, is an indicator equal to one for participants for whom neither parent has a college degree. Data are from the Romanian subject sample. Standard errors are robust to heteroskedasticity and are clustered by subject. \( \ast \), and \( \ast \ast \) indicate significance at the 5% and 10% level, respectively.

Active task, in loss condition blocks), the beliefs expressed by low SES participants are on average 4.70% (\( p < 0.05 \)) more pessimistic than those of mid or high SES participants. Unsurprisingly, in light of the prior literature on gender effects on investing (e.g., Barber and Odean, 2001), we also find that men have more optimistic assessments of the quality of the stock, relative to women, in most of the sample splits done in the analysis in Table 2.

To check whether these findings are robust to our measure of low SES, in Table 3 we conduct the same type of regression analyses as in Table 2 using the other three ways to measure SES discussed in Section 2. For ease of comparison, we present the coefficient estimates for our main low SES measure (obtained in Table 2) in Panel A of Table 3. We then assign participants to low socioeconomic status based on parental income (Panel B), subjective socioeconomic status evaluation (Panel C), or parental education (Panel D). The low SES measures in Panels A, B, and C have similar effects: lower SES participants, categorized this way using either of these three approaches, have more pessimistic beliefs regarding the quality of the stock when objectively the stock is likely to be a good investment. However, if SES is assessed solely based on whether or not neither parent of a participant got a college education, we no longer observe a significant pessimism bias in the low SES participants (i.e., those whose parents do not have college degrees). This suggests a possibility that needs investigation in further work, namely, that pessimism in assessing financial investments may be triggered by aspects of SES related to low income or financial difficulties, and not necessarily by a lack of formal higher education of one’s parents.

The evidence in Fig. 3 and Tables 2 and 3 indicates that low SES individuals form more pessimistic posterior beliefs about the likelihood that the stock they are presented with is paying dividends from the good distribution, when the stock is likely to be good. A natural question is why these posterior beliefs are more pessimistic for the low SES group. All participants were carefully instructed at the beginning of each learning block of six trials that the probability that the stock would pay from the good distribution, not the bad one, was 50%. Thus, by the design of the experiment, the priors were set to 50%, for all participants, no matter their socioeconomic status. Therefore, the observed SES-related difference in posterior beliefs needs to be driven by the process by which individuals from different SES levels update their beliefs about the quality of the stock, after observing its dividends.

In the regressions in Table 4 we find that indeed there is a difference in how low SES participants and the mid or high SES ones update their subjective beliefs after observing the stock outcome in a given trial. In particular, in the first column in the table we document that low SES participants’ subjective probability estimates are 3.15% (\( p < 0.06 \)) less sensitive relative to those of mid or high SES participants, to the presentation of high stock dividends. The second column in the table shows that updating after seeing low dividends does not significantly differ by SES level.
Table 4  
SES and differences in probability updating after high and after low dividends.

The dependent variable in the OLS regressions in the table is Probability estimate t, which is the subjective estimate for the probability that the stock pays from the good dividend distribution, given the dividend history seen by participant i up to and including trial t, in the Active version of the task. The variable Low SES i is an indicator equal to one for participants in the bottom third of the SES score distribution. Control variables Male, and Age, indicate the gender and age of participant i. Also included as a control in the first two columns is the subjective probability, expressed in trial t – 1, that the stock pays from the good distribution. The regressions in the last two columns include only data from the first trial in each learning block (i.e., ten trials per subject), for which the prior belief that the stock is the good one is 50%, as indicated to subjects in the experimental instructions detailed in Appendix A. That is, for observations in the last two columns, Probability estimate t−1 = 50% by experimental design. Data are from the Romanian subject sample. Standard errors are robust to heteroskedasticity and are clustered by subject. * , ** , and * * indicate significance at the 1%, 5%, and 10% level, respectively.

A particularly informative setting in which updating can be studied is that of the first trial in each of the ten learning blocks completed by each person. In the first trial of each learning block, everybody’s prior belief that the stock is the good one is set to 50%, by experimental design. In that first trial, the stock dividend is either high or low. If low SES participants update less from high dividends, we should observe that their subjective probability estimates after that first dividend in the learning block is revealed to be high will be lower than the estimates produced by mid or high SES participants who observe the same high dividend. The results in the third column of Table 4 present evidence consistent with this prediction: after seeing a high dividend in the first trial of a new learning block, low SES participants produce subjective probability estimates that are 4.53% (p < 0.08) lower than those of their mid or high SES counterparts. The last column in the table shows that when the first dividend in a new learning block is low, there is no significant difference in the posterior beliefs of participants, depending on their SES level.

Therefore, the evidence in Table 4 suggests that asymmetric updating is the likely mechanism through which low SES participants become pessimistic regarding the quality of the financial assets available to them, when these assets are in fact good: they do not update as much as the higher SES participants from news that indicates that these assets are of good quality. That is, low SES participants may have a skewed view of the financial investments surrounding them: more of a view akin to “the glass is half-empty” rather than “the glass is half-full”, consistent with neuroscience evidence that adverse environments predispose the brain to react relatively less to good outcomes compared to bad outcomes (e.g., Nusslock and Miller, 2016).

Our results therefore indicate that low SES is associated with conditional pessimism: when the stock is objectively not likely to be a good investment, both low SES and high SES subjects have beliefs about the stock that are statistically not different. However, when the stock is objectively likely to be a good investment, with a good dividend distribution, this is when we find that the low SES subjects are more pessimistic about the stock than the other subjects. In other words, relating this result to real-life economic behavior, our laboratory findings suggest that when the financial environment is difficult (e.g., during a financial crisis or economic downturn), both low and high SES people are equally good at acknowledging that the fundamentals of the assets in the markets are poor. However, when the financial environment is good (e.g., when not in a financial crisis or economic downturn), high SES people are good at acknowledging that positive reality, but low SES people are reluctant to acknowledge it. Thus, our conditional pessimism result suggests that low SES people may be reluctant to have high expectations when the environment around them actually suggests that, fundamentally, investment opportunities are good.

This implication lines up well with findings from psychology and neuroscience. In the psychology literature, Taylor and Seeman (1999), Robb et al. (2009) and Chen et al. (2004) document evidence indicating that low SES people are more likely to focus on the potential downside when the situation around them objectively seems good, but in bad situations there is no SES effect on people’s assessments of the expected outcome. In the neuroscience literature, Hanson et al. (2016) find that people who have faced more adversity show less activation in a brain region critical for learning about one’s environment when receiving positive feedback, but no such difference is observed upon receiving negative feedback.5

5 The neurotransmitter that generates the activation of this brain region, namely, dopamine, has been shown to be causally involved in learning from positive outcomes (Pessiglione et al., 2006). Adverse life events
This conditional pessimism that we document to be related to lower SES also has implications for the time variation in SES-related differences in beliefs about the stock market, and in SES-related differences in stock investments. Specifically, our experimental results imply that the beliefs regarding stock market returns, as well as stock market exposures, will be more similar across SES levels during financial crises or economic downturns, and will be more dispersed across SES levels during normal times. The evidence in Hoopes et al. (2016) supports these implications. There, the authors document that during the 2008–2009 financial crisis investors at the top of the income distribution were significantly more likely to sell stocks than the less well-off investors, which would lead to less dispersion in stock market exposure across SES levels during the crisis than during normal market conditions.

Aside from being more pessimistic in their beliefs regarding the stocks presented during the experiment, we also find that low SES participants differ from the mid or high SES ones in terms of the rate at which they improve their probability estimation performance over time. Specifically, the rate of improvement during the 20 blocks of the experiment is lower among low SES individuals, compared to mid and high SES individuals. Fig. 4 shows the average absolute estimation errors for each of the 20 learning blocks, for the low SES and the mid and high SES groups of subjects, separately, as well as the estimated linear relationship between the learning block number and the absolute estimation errors for each of these two groups. For low SES subjects, probability estimates are on average 35.45% away from Bayesian posteriors in the first learning block they encounter, and then these subjects’ estimation errors decrease at an average rate of 0.2% per block. For mid or high SES subjects, probability estimates are on average 32.08% away from Bayesian posteriors in the first learning block they encounter, and then their estimation errors decrease at an average rate of 0.35% per block. The rate of improvement in probability estimation for low SES participants is significantly lower than that for mid or high SES participants (p < 0.05). The figure also shows that learning slows down towards the very end of the experiment. Specifically, for both the low SES and the mid and high SES groups, their best performance measured as the average of the absolute probability error occurs in block 18, when the average absolute estimation error is 28.27% for low SES subjects, and 25.50% for mid and high SES subjects, and does not improve in the remaining two learning blocks. The improvement in estimation shown by participants makes it possible that the size of the SES-related conditional pessimism effect may change as subjects gain more experience with the task. To the extent that the negative view about stocks expressed by low SES individuals reflects a strong predisposition stemming from these people’s experiences, it is unlikely that this view will change during the course of a short experiment. We formally test whether the size of the SES-related wedge in beliefs changes from the beginning to the end of the experiment by estimating similar regression models as in Tables 2 and 3 where we additionally introduce an
interaction term between the indicator of low socioeconomic status and the block number, and we also control for the block number itself. As expected given the short duration of the experiment, in these additional regressions (omitted here for brevity) we find that the conditional pessimism effect that is related to having a low SES does not change significantly as the task progresses.\(^6\)

Moreover, we find that throughout the experiment there is persistence within subjects with respect to how pessimistic or optimistic they are in assessing the probability that the stock is paying from the good dividend distribution. For each subject, we calculate the average of their probability errors across trials, where in each trial the error is measured as the subjective estimate minus the objective probability. We calculate this average error in the first ten learning blocks of the experiment, and in the last ten blocks, and also, separately for trials when the objective probability was greater than or equal to 50%, and when it was smaller than 50%. We find that in situations when the objective probability was greater than or equal to 50%, the correlation between errors made by participants in the early and the late blocks is 0.42 (\(p < 0.01\)), and in situations when the objective probability was less than 50%, this correlation is 0.31 (significant at \(p < 0.01\)). In other words, irrespective of the correct posterior belief, subjects show consistency during the experiment in terms of how high or how low their own estimates are relative to the correct posteriors.

3.2. Replication study in a different experimental sample

To examine whether the results obtained in the original sample of participants replicate in other populations, we recruited 33 participants from the University of North Carolina at Chapel Hill. These U.S.-based individuals completed the Active version of the experiment only, as the original Romanian sample results indicated no SES effects in the Passive version. The Active task was identical to that used in the Romanian sample, except for having the stock and bond payoffs expressed in U.S. dollars, instead of RON. As done in the original sample, in the replication sample we assign participants to the low SES category if they have SES scores which are in the bottom third of the distribution.

We find that in the U.S. sample, people from a low SES background form more pessimistic estimates of the probability that they are faced with the stock, relative to those from middle or high SES backgrounds, when the stock is likely to be a good investment. This result, which replicates the main finding from the Romanian sample documented in Table 2, is shown in Table 5. As in the original sample, in the replication sample we find that the effect of low SES on subjective beliefs about the stock is particularly large during loss condition trials, when participants face negative outcomes.

Thus, across two samples in two different countries, we document that coming from more economically disadvantaged backgrounds predicts that people will have a more pessimistic assessment regarding the outcomes of financial investments available to them in our experimental setting, exactly in situations when these investments are in fact likely to be good.

3.3. Alternative explanations

3.3.1. Do risk aversion and finance knowledge differ across SES categories?

While the evidence so far suggests that low SES participants form opinions about the quality of investment opportunities differently from mid or high SES participants, it is possible that there are other SES-related factors, unrelated to updating, that would lead to these differences in subjective probability estimates in the low SES versus the mid or high SES group. For example, it could be that low SES participants are not more pessimistic in how they update their view about investments, but they have lower levels of finance-related knowledge that would allow them to do well in this learning task. We find that this is not the case in our sample. We use four measures of finance-relevant knowledge: the subjects’ scores on the financial knowledge questions detailed in Section 2, their numeracy score calculated as in Peters et al. (2006), the type of college major they pursued (technical or not), and the average confidence they reported when expressing their probability estimate in every trial. Table 6 presents averages of these four variables related to the subjects’ understanding of finance-relevant concepts, separately for the low SES subsample, and the mid or high SES subsample. We find that neither one of these four dimensions of finance-relevant knowledge differs significantly across the two subsamples, as shown by the \(p\)-values in the last column in the table.

Another potential explanation for our main effect is that perhaps low SES participants are more risk-averse than the mid or high SES participants, and their subjective probability estimates reflect their increased risk aversion, and not pessimism in their true beliefs. We analyze four measures of risk aversion to see whether they are different for the low SES group relative to the rest of participants.

First, for each person we calculate the frequency with which they chose the stock, rather than the bond, in the first trial in each learning block. In this trial the choice is solely driven by risk preferences and not by new information, since no dividend of the stock has yet been observed, and thus participants only know the 50% prior that the stock is the good one. As shown in the first row of Table 7, the difference in the propensity to chose the stock in the first trial between the low SES group and the other participants is not significantly different from zero at conventional levels. Second, we compare the amount, out of a hypothetical 10,000 RON endowment, that subjects would invest in the stock market, for the low SES group and the mid or high SES group, and again find no significant difference, as shown in the second row of the table. The third and fourth measures of risk attitudes shown in the bottom two rows of Table 7 are given by subjects’ scores on

\(^6\) That being said, it is possible that with enough exposure to certain financial decision-making situations this conditional pessimism may disappear. It is our hopeful conjecture that through experience with financial investments, individuals can overcome biases in beliefs about the stock market, and we leave it to future work to investigate this possibility.
Table 5
Probability estimates and SES—U.S. experimental laboratory replication sample.
The dependent variable in the OLS regressions in the table is Probability estimate_{it}, which is the subjective estimate for the probability that the stock pays from the good dividend distribution, given the dividend history seen by participant i up to and including trial t. The variable Low SES_{i} is an indicator equal to one for participants in the bottom third of the SES score distribution in the replication sample of U.S.-based participants. These individuals completed the Active version of the task only. Control variables Male_{i} and Age_{i} indicate the gender and age of participant i. Also included as controls are fixed effects for each level of the objective Bayesian posterior probability that the stock pays from the good distribution, given the 50% prior and the history of stock dividends observed by participant i up to and including trial t (Objective probability_{it}). Data are from the U.S. experimental subject sample. Standard errors are robust to heteroskedasticity and are clustered by subject. **, *, and † indicate significance at the 5% and 10% level, respectively.

two surveys used widely in the psychology literature, the State-Trait Anxiety Inventory (Spielberger et al., 1983) and the Behavioral Inhibition Scale (Carver and White, 1994). We do not find any differences between the low SES and the mid or high SES groups on these anxiety-related proxies for risk avoidance.

Furthermore, as a robustness check we include the personal characteristics from Tables 6 and 7, such as finance knowledge and risk aversion, as additional explanatory variables in our main analysis in Table 2 and continue to find that the effect of low SES on the subjective probability that the stock is the good one is negative and significant (full estimation results omitted here for brevity). For example, after adding financial knowledge, numeracy, an indicator for whether the participant pursues a technical college major, and the state and trait anxiety measures to the regression in column 2 of Table 2, the effect of low SES on the subjective probability estimate is -3.43% (t-stat = -2.34), similar to the effect found without these additional explanatory variables (-2.85%, t-stat=1.98).

3.3.2. Do low SES participants exhibit pessimism or are they in general less able to update correctly?

If low SES participants were simply less able to update, their probability estimates would be significantly higher than those of mid and high SES participants in situations when the objective probability that the stock is the good one is less than 50%. However, as Fig. 3 shows, this is not the case. That is, when the stock is unlikely to be the good one, the estimates of both types of participants are equally far from the correct, objective probability. The same conclusion can be drawn when comparing the first two columns in Tables 2, 3, and 5. Specifically, across the original Romanian sample and the replication sample in the US, using various measures of SES, the evidence points to relative pessimism on behalf of low SES participants relative to mid and high SES ones when the stock is likely to be the good one, but not to relative optimism when the stock is unlikely to be good. Hence, we do not find evidence of a general lack of updating ability among low SES participants, but rather, we find evidence consistent with belief errors in a specific direction, namely, that of pessimism about the stock return distribution in situations when objectively the stock is likely to have good outcomes.

3.4. Consequences for investment choices

The pessimistic assessment of the quality of the stock payoff distribution observed among the low SES participants has consequences for these individuals’ investment choices. Specifically, as shown in Fig. 5, low SES individuals are significantly less likely to choose the stock, particularly in trials when the objective probability that the stock is paying from the good dividend distribution is greater than 50%. In such trials, risk-neutral expected value-maximizing investors would choose to hold the stock rather than the bond. However, we find that in these situations low SES participants choose the stock, rather than the bond, in 74% of the trials, whereas the mid and high SES participants choose the stock in 79% of the trials (the difference is significant at p < 0.05). That is, in cases when the stock is the optimal investment choice given the dividends observed so far, low SES participants are less likely to choose the stock compared to their mid and high SES peers, and thus get a smaller payoff by choosing the bond.

3.5. External validity test: large sample evidence from the US.

The evidence from our laboratory experiment run in Romania and replicated in the U.S. indicates that lower SES experiment participants are more pessimistic in their assessment of the available stock investment and less willing to choose the stock over the bond, when the stock is likely to be a good investment. The natural next step is to inquire whether these findings are also present among populations outside of college laboratory samples, in situations when people are considering actual stocks instead of experimental assets, and whether our findings are robust to other ways in which a person’s SES is measured.

Since the participants in the experimental task in the laboratory were all college students (thus young and not

---

7 In the Romanian laboratory sample we observed that subjects sometimes chose the stock instead of the bond even in situations when the objective probability that the stock was the good one was strictly less than 50%, and hence the bond would have been the optimal choice for a risk-neutral agent, as can be inferred from Fig. 5. This tendency was reduced, yet not completely, in the U.S. laboratory sample, which may indicate an interesting cultural difference in people’s approach to investment decisions, something which we leave for future research to examine in depth.
yet fully employed or fully educated), for these individuals we measured their SES based on the demographic characteristics (e.g., income and education) of their parents. It is thus important to check whether in older samples of individuals, who vary in SES because of their own (not their parents’) income, education, or other circumstances, we still observe that lower SES people view stocks in a more pessimistic manner and are less likely to invest in them.

To test the external validity of the findings of our experiment, we contracted with Qualtrics, a well-known provider of online survey services, to recruit on our behalf approximately 1,200 individuals across all 50 U.S. states, across ages 18–65, and across all income levels such as to be representative of the income distribution according to the U.S. Census. Each of the 1,200 individuals who were in the final sample provided by Qualtrics, recruited during April-May 2015 from 591 different counties across all U.S. states, answered several demographics questions. These questions, which are detailed in Appendix D, included asking participants about their age, gender, education, income level, zip code of residence, and history of financial difficulties since 2007, the beginning of the recent economic turmoil.

The sample characteristics are presented in Table 8 and indicate that the individuals recruited by Qualtrics are indeed very diverse and representative of the U.S. population. Household income is below $15,000 for 13.42% of participants and above $100,000 for 18.89% of participants, with other income levels being also very well represented in the sample. In terms of education, 41.34% of participants have a college degree. Males represent 51.20% of the sample. Participants’ ages vary from 18 to 65, with middle-aged people being the most represented; for example, people with ages between 30–39 years old make up 21.96% of the sample, and those with ages 40–49 years old make up 22.45% of the sample. About 45.15% of the sample reported having at least one of seven types of financial difficulties since 2007. The seven types of financial difficulties we asked participants about are: bankruptcy, foreclosure of property, loss of employment, the inability to pay debts on time, difficulty getting approved for loans, for example, to buy a car or a house, having accounts in collection, or borrowing from a payday lender.

After the demographics-related questions, participants were asked two additional questions, to elicit their beliefs about the possible outcomes of investing in the U.S. stock market, and their actual investment choices. These two questions were worded as in the Michigan Survey of Consumers, which has provided an aggregate index of consumer sentiment for many years, and are as follows: (1) “What do you think is the percent chance that a $1,000 investment in a diversified stock mutual fund will increase in value in the year ahead, so that it is worth more than $1,000 one year from now?”; and (2) “Currently, what percentage of your income do you invest in the stock market? Include

investments in directly owned stocks, stocks in mutual funds and stocks in retirement accounts, such as 401(K)s or IRAs.”

Question (1) above reveals the subjective probability of the individual that the aggregate U.S. stock market will have a positive return over the following year, and this quantity is a good real-life parallel to the subjective probability estimate that the participants in the laboratory experiment had to provide. That is, both in the sample of experimental subjects and in the regular adult sample surveyed by Qualtrics, we obtain a measure of people’s belief that stocks are good investments. Question (2) above measures the individual’s actual investment behavior, in terms of their decision to invest in stocks, and it is the real-life parallel of the measure we used in the laboratory experiment, which referred to people’s decision to choose the stock instead of the bond in any given trial.

If our laboratory findings have external validity, then we should observe that in the sample of 1,207 adults surveyed by Qualtrics on our behalf, the lower SES individuals would have a more pessimistic assessment of the probability that the U.S. stock market would have a positive return over the subsequent year, and would invest a lower fraction of their income in stocks. As shown in Fig. 6 the data provide strong support for these predictions. In the figure we present the participants’ answers to questions (1) and (2) above—namely, their belief about stock investments, and the share of income they invest in stocks—for different subsamples of individuals based on their SES level. As our measure of participants’ SES, we use their household income in the top panel of Fig. 6, education in the middle panel of Fig. 6, and whether or not since 2007 they encountered any of the seven types of financial difficulties listed above, in the bottom panel. No matter which SES measure we use, we find that adults with lower SES indeed have more pessimistic beliefs about the U.S. stock market and they invest a lower percentage of their income in stocks. For example, the data in the top panel of Fig. 6 show that people whose household income is in the lowest tercile in the sample (i.e., under $35,000) on average estimate the probability that the U.S. stock market will have a positive return over the following year to be 47.70%, whereas the same subjective estimate is 58.69% for people whose household income is in the highest tercile (i.e., $75,000 or higher). These probability estimates are significantly different at p < 0.01. People in the middle tercile of income also report significantly lower probability estimates than those in the top tercile (49.33% vs. 58.69%, p < 0.01). Importantly, not only do those earning less have a more pessimistic assessment of the U.S. stock market, but they also invest a lower share of their income in stocks. Specifically, we find that the average share of income invested in stocks is 7.94% for people in the lowest income tercile, 11.8% for people in the middle income tercile, and 21.59% for people in the top income tercile. The differences between the income share invested in stocks of individuals in the top income tercile and those in the lowest two income terciles are significant at p < 0.01.

The same pattern emerges when we measure SES by education, or by the presence of financial difficulties in the recent recession since 2007. The middle panel of Fig. 6 shows that college-educated participants assess on average the probability that the U.S. stock market would have a positive return over the following year to be 55.46%, whereas the estimate provided by people without a college degree is 48.73% (the difference is significant at p < 0.01). Moreover, college-educated participants invest on average 19.07% of their income in stocks, whereas people without a college degree invest on average only 9.24% of their income in stocks (the difference is significant at p < 0.01). The data in the bottom panel of Fig. 6 show that individuals who have not encountered financial difficulties since 2007 assess on average the probability that the U.S. stock market will have a positive return over the next year to be 53.05%, whereas the estimate of those who have encountered financial difficulties since 2007 is 49.65% (the p-value of the difference is 0.08). Those participants without financial difficulties invest on average 16.79% of their income in stocks, whereas those who have encountered financial trouble invest only 9.07% of their income in stocks (the difference is significant at p < 0.01).

This evidence strongly indicates that the survey participants with lower SES are more pessimistic about the stock market and less inclined to invest in stocks, thus supporting the findings from our experimental laboratory setting. However, there exists the concern that perhaps those individuals we surveyed were not truthful about their income, education, or financial troubles and biased their answers in such a way that we ended up observing those reporting lower SES also reporting more pessimistic beliefs about stocks and a reluctance to invest in stocks. While we have no reason to believe that misreporting happened, and that it happened in this very specific manner that would drive all the results in Fig. 6, it is important to investigate if our results disappear once we have objective measures of these individuals’ SES. Luckily, we can do this, as in the survey we asked participants (before they saw any questions about their income, financial troubles, or the stock market) to tell us the five-digit zipcode in which they reside.8 We then identified the county to which each zipcode belongs.9 This allows us to obtain county-level data from the American Community Survey conducted by the U.S. Census regarding each county’s demographics and economic conditions. The data are from the 2013 release (the latest available at the time this paper is written) and provide county-level measurements of income, education, or unemployment as five-year averages over the 2009–2013 window (one-year estimates are also available but only for the very largest of counties in the US). These objective county-level measures can therefore provide us with instruments for our survey participants’ income, education, and economic adversity in general, and thus will alleviate the concern that the self-reported SES measures we get from these individuals are biased or mismeasured in general.

With these objective, county-level SES measurements in hand, in the analysis presented in Fig. 7 we conduct

---

8 This information can be verified using the geolocation information provided by Qualtrics based on the IP address of each survey participant.

9 To map zipcodes to counties, we used the HUD-USPS ZIP Code Crosswalk Files available at www.huduser.gov. If a zipcode stretches across multiple counties, which happens rarely, we assigned to that zipcode the county where more than 50% of the zipcode’s residents live.
Fig. 6. External validity check using the U.S. survey sample. Data are split by the participants’ tercile of self-reported income (top panel), education level (middle panel), and the experience of recent financial difficulties (bottom panel). Means and standard errors are shown for each subsample.
Fig. 7. External validity check using the U.S. survey sample, corroborated with U.S. Census data. Data are split by the participants’ tercile of county median household income (top panel), county education level (middle panel), and county unemployment rate (bottom panel). County data are from the U.S. Census American Community Survey and refer to five-year averages calculated for each county during 2009–2013. Means and standard errors are shown for each subsample.
the same type of comparisons as in Fig. 6, but instead of the participants’ self-reported SES measures we use the county-level measures from the U.S. Census. The results in the two figures are very similar. Even when instrumenting the participants’ SES with county-level SES indicators, we continue to find that people in worse economic situations, namely, people living in counties with lower income, lower education, or higher unemployment, have a more pessimistic assessment about the U.S. stock market return over the following year and invest less of their income in stocks. Specifically, the top panel of Fig. 7 shows that participants in the bottom tercile in terms of county-level median household income assess the probability that the U.S. stock market will have a positive return in the next year to be 48.91%, whereas those in the top tercile assess that probability to be 54.24% (the difference is significant at $p < 0.05$). These groups also invest differently: those in the bottom tercile, namely, living in counties with a low median household income, invest 11.02% of their income in stocks, whereas those in the top tercile invest 15.86% of their income in stocks (the difference is significant at $p < 0.01$). The middle panel of Fig. 7 shows that people living in counties with below-median college education rates express lower probabilities about the stock market having a positive return, relative to those living in counties with above-median college education (48.98% vs. 54.15%, difference significant at $p < 0.01$), and also invest less of their income in stocks (10.74% vs. 16.03%, difference significant at $p < 0.01$). The bottom panel of Fig. 7 shows that county-level unemployment is also a predictor of people’s beliefs about the stock market, as we find that among participants in counties with above-median unemployment, the average subjective probability that the U.S. stock market will have a positive return over the next year is 49.50%, whereas among those in counties with below-median unemployment the average subjective probability is 53.54% (the difference is significant at $p < 0.05$).

Finally, as a check for the internal consistency of the U.S. survey data, we investigate whether the beliefs expressed by the 1,207 survey participants predict their stock investment choices. As expected, there is a strong positive correlation ($\rho = 0.19$, significant at the 1% level) between the participants’ subjective probability estimates of a positive U.S. stock market return in the next year and the percent of income they say they invest in stocks. This relationship is also illustrated in Fig. 8. To construct that figure, we assigned each of the 1207 participants to a belief quintile (spanning the 0% to 100% range), depending on the value of his/her subjective probability estimate of a positive U.S. stock market return in the following year. The figure shows the positive dependence of the fraction of income invested in stocks (averaged across all people whose beliefs fell into a particular quintile) on the beliefs expressed by these people regarding future stock market returns. For example, individuals who assessed that the probability of a positive U.S. stock market return in the following year is between 80% and 100% declared, on average, that they invest 18% of their income in stocks. For individuals who assessed this probability to be between 0% and 20%, the average fraction of income invested in stocks is only 8% (the difference is significant at $p < 0.01$). Therefore, we find that participants’ beliefs help predict their investment choices, which suggests that the U.S. survey data are internally consistent.

Overall, therefore, we find consistent evidence in support of the hypothesis of the paper, which is that people from lower SES environments, or those characterized by more economic adversity, have a more pessimistic assessment of the stock market and are more reluctant to invest in stocks, when fundamentally these assets appear to be good. This evidence comes from controlled experimental settings in two different countries, as well as from a large sample of participants from all of 50 states in the U.S., which suggests that these results are robust, have external validity, and describe actual households’ beliefs and investment decisions.

4. Implications and conclusion

Building on insights from neuroscience which suggest that encountering adversity biases the brain to respond less to positive outcomes relative to negative ones, we test the hypothesis that individuals who have faced more economic adversity will have more pessimistic beliefs regarding the possible returns of financial investments and will be less inclined to invest in risky assets such as stocks.

In line with this hypothesis, we find that individuals with lower socioeconomic status are more pessimistic compared to their more economically advantaged peers when assessing the distribution of stock investment outcomes and invest less in stocks, specifically in situations when these investments are likely to be good. SES-related differences in beliefs are robust to several ways of measuring one’s socioeconomic standing and do not arise from differences in risk preferences or finance-relevant knowledge. Rather, we document that SES induces an asymmetry in how people learn from new stock outcomes. Specifically, we find that low SES participants are less likely to update their beliefs about the quality of the distribution of stock outcomes when good news about stocks is revealed.

We replicate these results in two different controlled experimental settings in Romania and the U.S. and then also show their external validity in a large sample of adults across all 50 U.S. states. Namely, we find that adults with lower income, lower education, who have faced significant negative financial shocks during the recent economic downturn, or live in counties with worse economic conditions, assess a lower probability that the aggregate U.S. stock market will have a positive return over the following year, and invest a lower share of their income in stocks.

It would be useful for future work to investigate the importance of the effect of SES on beliefs about stocks for investment decisions of households measured over a long horizon, and for the evolution of wealth inequality in the population. As argued by Campbell (2016) and Lusardi et al. (2017), if poorer people invest ineffectively, their wealth will grow more slowly than the wealth of richer people even if they have the same savings rates. Hence, SES-related dispersion in beliefs about stock investments is likely to have an impact on the dynamics of wealth inequality.

Furthermore, it remains to be established which aspects of economic adversity matter more for the beliefs
that households form regarding financial investments, and how this may vary in different age groups. For example, as Cronqvist and Siegel (2015) show that the influence of the early-life environment on people’s savings behavior is highest among people in their twenties, it is thus possible that among older adults, beliefs about financial asset returns may be driven more by their own, rather than their parents’, socioeconomic status. Also, here we document that economic conditions in the counties where people reside influence their beliefs about the stock market, in that people who reside in poorer or less educated counties have a more pessimistic assessment of the distribution of future stock returns. It would be interesting to analyze whether and how local economic conditions modulate the effect of a person’s own SES on their beliefs about the stock market or other economic expectations.

Our findings are important for understanding the low rates of stock market participation observed among low SES households (Campbell, 2006; and Calvet et al., 2007). Our results indicate that coming from a background characterized by high economic adversity induces people to view financial matters through a pessimistic, “glass is half-empty”, lens rather than in an unbiased manner, which may have negative consequences on wealth accumulation. Hence, another avenue for future work is to examine interventions that can help reduce the SES-related bias in people’s beliefs about the distribution of outcomes of risky investments.

**Appendix A. Participant instructions (English translation)**

**Welcome to our financial decision making study!**

In this study you will work on two investment tasks. In one task you will repeatedly invest in one of two securities: a risky security (i.e., a stock with risky payoffs) and a riskless security (i.e., a bond with a known payoff), and will provide estimates as to how good an investment the risky security is. In the other task you are only asked to provide estimates as to how good an investment the risky security is, after observing its payoffs.

In either task, there are two types of conditions you can face: the GAIN and the LOSS conditions. In the GAIN condition, the two securities will only provide POSITIVE payoffs. In the LOSS condition, the two securities will only provide NEGATIVE payoffs.

**Details for the investment choice and investment evaluation task:**

**Specific details for the GAIN condition:**

In the GAIN condition, on any trial, if you choose to invest in the bond, you get a payoff of 6 RON for sure at the end of the trial. If you choose to invest in the stock, you will receive a dividend which can be either 10 RON or 2 RON.
The stock can either be good or bad, and this will determine the likelihood of its dividend being high or low. If the stock is good then the probability of receiving the 10 RON dividend is 70% and the probability of receiving the 2 RON dividend is 30%. The dividends paid by this stock are independent from trial to trial, but come from this exact distribution. In other words, once it is determined by the computer that the stock is good, then on each trial the odds of the dividend being 10 RON are 70%, and the odds of it being 2 RON are 30%. 

**Specific details for the LOSS condition:**

In the LOSS condition, on any trial, if you choose to invest in the bond, you get a payoff of −6 RON for sure at the end of the trial. If you choose to invest in the stock, you will receive a dividend which can be either −10 RON or −2 RON.

The stock can either be good or bad, and this will determine the likelihood of its dividend being high or low. If the stock is good then the probability of receiving the −10 RON dividend is 30% and the probability of receiving the −2 RON dividend is 70%. The dividends paid by this stock are independent from trial to trial, but come from this exact distribution. In other words, once it is determined by the computer that the stock is good, then on each trial the odds of the dividend being −10 RON are 30%, and the odds of it being −2 RON are 70%.

**In both GAIN and LOSS conditions:**

In each condition, at the beginning of each block of 6 trials, you do not know which type of stock the computer selected for that block. You may be facing the good stock, or the bad stock, with equal probability.

On each trial in the block you will decide whether you want to invest in the stock for that trial and accumulate the dividend paid by the stock, or invest in the riskless security and add the known payoff to your task earnings. You will then see the dividend paid by the stock, no matter if you chose the stock or the bond.

After that we will ask you to tell us two things: (1) what you think is the probability that the stock is the good one (the answer must be a number between 0 and 100 - do not add the % sign, just type in the value); (2) how much you trust your ability to come up with the correct probability estimate that the stock is good. In other words, we want to know how confident you are that the probability you estimated is correct. (The answer is between 1 and 9, with 1 meaning you have the lowest amount of confidence in your estimate, and 9 meaning you have the highest level of confidence in your ability to come up with the right probability estimate.)

There is always an objective, correct, probability that the stock is good, which depends on the history of dividends paid by the stock already. For instance, at the beginning of each block of trials, the probability that the stock is good is exactly 50%, and there is no doubt about this value.

As you observe the dividends paid by the stock you will update your belief whether or not the stock is good. It may be that after a series of good dividends, you think the probability of the stock being good is 75%. However, how much you trust your ability to calculate this probability could vary. Sometimes you may not be too confident in the probability estimate you calculated and sometimes you may be highly confident in this estimate. For instance, at the very beginning of each block, the probability of the stock being good is 50% and you should be highly confident in this number because you are told that the computer just picked at random the type of stock you will see in the block, and nothing else has happened since then.

Every time you provide us with a probability estimate that is within 5% of the correct value (e.g., correct probability is 80% and you say 84%, or 75%) we will add 10 cents to your payment for taking part in this study.

Throughout the task you will be told how much you have accumulated through dividends paid by the stock or bond you chose up to that point.

**Details for the investment evaluation task:**

This task is exactly as the task described above, except for the fact that you will not be making any investment choices. You will observe the dividends paid by the stock in either the GAIN or the LOSS conditions, and you will be asked to provide us with your probability estimate that the stock is good, and your confidence in this estimate. In this task, therefore, your payment only depends on the accuracy of your probability estimates.

**Your final pay for completing the investment tasks will be:**

\[ 27 \text{ RON} + 1/10 \times \text{Investment Payoffs} + 1/10 \times \text{Number of accurate probability estimates} \times \text{where Investment Payoffs} = \text{Dividends of securities you chose in the experiment, in both the GAIN and the LOSS conditions.} \]

**Appendix B. Objective Bayesian posterior beliefs**

The table below provides all possible values for the objectively correct Bayesian posterior that the stock is paying from the good dividend distribution, starting with a 50%–50% prior, and after observing each possible dividend history path in a learning block. Every trial a new dividend (high or low) is revealed. There are six trials in each learning block.

The objective Bayesian posterior that the stock is the good one, after observing \( h \) high outcomes in \( n \) trials so far is given by:

\[ p = \frac{1}{1 + \frac{1}{\frac{p}{1-p} + \frac{1}{p^{n-h}-q^n}}} \]

where \( p = 50\% \) is the prior that the stock is good (before any dividends are observed in that learning block) and \( q = 70\% \) is the probability that
a good stock pays the high (rather than the low) dividend in each trial.

Appendix C. Measures of financial literacy and risk preferences

To get measures of financial literacy and risk preferences, each participant was asked the following questions after the completion of the experimental tasks: “Imagine you have saved 10,000 RON. You can now invest this money over the next year using two investment options: a stock index mutual fund which tracks the performance of the stock market, and a savings account. The annual return per dollar invested in the stock index fund will be either +40% or −20%, with equal probability. In other words, it is equally likely that for each RON you invest in the stock market, at the end of the one year investment period, you will have either gained 40 cents, or lost 20 cents. For the savings account, the known and certain rate of return for a one year investment is 5%. In other words, for each RON you put in the savings account today, for sure you will gain 5 cents at the end of the one year investment period. We assume that whatever amount you do not invest in stocks will be invested in the savings account and will earn the risk free rate of return. Given this information, how much of the 10,000 RON will you invest in the stock index fund? Choose an answer that you would be comfortable with if this was a real-life investment decision. The answer should be a number between 0 and 10,000 RON.”

After each participant wrote their answer to this question, they were asked the following: “Let’s say that when you answered the prior question you decided to invest x RON out of the 10,000 RON amount in the stock index fund, and therefore you put (10,000 − x) RON in the savings account. Recall that over the next year the rate of return on the stock index fund will be +40% or −20%, with equal probability. For the savings account, the rate of return is 5% for sure. What is the amount of money you expect to have at the end of this one year investment period? Please choose one of the answers below. If you choose the correct answer, you will get a 5 RON bonus added to your pay for this experiment: [A]. 0.5 (0.4 x −0.2 x) + 0.05 (10,000−x) [B]. 1.4 x + 0.8 x + 1.05 (10,000−x) [C]. 0.4 (10,000−x) − 0.2 (10,000−x) + 0.05 x; [D]. 0.5 [0.4 (10,000−x) −0.2 (10,000−x)] + 0.05 x; [E]. 0.4 x −0.2 x + 0.05 (10,000−x); [F]. 0.5 (1.4 x + 0.8 x) + 1.05 (10,000−x); [G]. 1.4 (10,000−x) + 0.8 (10,000−x) + 1.05 x; [H]. 0.5 [1.4 (10,000−x) + 0.8 (10,000−x)] + 1.05 x.”

The correct answer to this question is [F]. The actual choices (if other than [F]) made by participants indicate three different types of errors that can occur when calculating the expected value of their portfolio holdings: the lack of understanding of statements regarding probabilities (answers [B], [C], [E], [G]); the lack of understanding of the difference between net and gross returns (answers [A],[C], [D], and [E]); and confusing the stock versus risk-free asset investments (answers [C], [D], [G], and [H]). Therefore, a financial knowledge score varying between zero and three can be constructed, based on the number of different types of errors contained in the answer provided by each participant (i.e., zero errors for answer [F], one error for answers [A], [B], and [H], two errors for answers [D], [E], and [G], and three for answer [C]). Hence a financial knowledge score of three indicates a perfect answer, while a score of zero indicates that the participant’s answer included all three possible types of errors.

Appendix D. Large sample survey (Qualtrics) questions

We contracted with the outside firm Qualtrics, using their Panels service, for them to recruit on our behalf approximately 1,200 individuals ages 18–65 from across the U.S.A. and across income levels such as to have the income distribution be representative of the population according to the U.S. Census. These individuals were invited by Qualtrics Panels to take part in our short survey, during April-May 2015. The survey questions were as follows:

**What is your age?** 18–22 years old/23–29 years old/30–39 years old/40–49 years old/50-59 years old/60–65 years old

**What is your gender? Male/Female**

What is the highest level of education you have completed? Some high school/GED/completed high school/some college/technical and/or associates degree/college degree/some post-graduate work/post-graduate degree/Other (please specify)

To which racial or ethnic group do you most identify? African-American (non-Hispanic)/Asian/Pacific Islanders/ Caucasian (non-Hispanic)/Latino or Hispanic/ Native American or American Indian/Other (please specify)

In which zip code do you currently reside? Please enter your 5-digit zip code: ______

Which of the following best describes your current employment status? Employed for wages/Self-employed/ Unemployed and looking for work/Unemployed and not looking for work/Stay-at-home caregiver/Student/Military/
Retired/Unable to work due to disability/Other (please specify)

Follow up question if unemployed: For how many months have you been unemployed?
